Causal Geometry of an Alg-Zoo RNN: A Mechanistic Case Study

Integrating Causal Ablation, Temporal Dynamics, and Topological Analysis

Kishore Kumar Mariappan, M.Sc.

March 8, 2026

Abstract

A central bottleneck in mechanistic interpretability is the reliance on sparse circuit discovery, which often fails to explain dense, distributed representations. We present a mechanistic case study of the 432-parameter "Alg-Zoo" RNN ($M_{16,10}$), a model that famously resisted sparse analysis. Introducing the **Topological Circuit Audit (TCA)**, we demonstrate that the network's computation is governed by a continuous, distributed **invariant manifold** (the "Logic Ring"). By modeling the network as a piecewise-linear dynamical system, we prove the ring acts as a stable center manifold ($R^2 = 1.000$). We derive a mechanistic error bound of **3.44%** from the manifold's geometric resolution limit—quantitatively matching empirical performance. Finally, we move from correlation to causation via a controlled topological pinch test, isolating a 10.6% logic gap that proves the manifold's orthogonal geometry is strictly load-bearing. This establishes that for analog tasks, the fundamental unit of computation is the manifold, not the neuron.

1 Introduction: Beyond Sparse Circuits

In 2026, the Alignment Research Center (ARC) released "Alg-Zoo," a benchmark suite of small models designed to stress-test interpretability techniques [1]. While sparse circuit analysis [2] succeeded on minimal networks, it hit a wall with the 432-parameter variant ($M_{16,10}$) trained on the `2nd-argmax` task. Despite its small size, the model's logic appeared "smeared" across all neurons, defying decomposition into discrete subgraphs.

We propose that this failure stems from the **Sparsity Illusion**: the assumption that all intelligible algorithms must be implemented via sparse connectivity. We hypothesize that for continuous magnitude-based tasks, gradient descent favors **distributed geometric representations** governed by attractor dynamics.

To reverse-engineer such systems, we introduce the **Topological Circuit Audit (TCA)**. Bridging Singular Learning Theory (SLT) [3], Dynamical Systems [4], and Causal Inference [7], TCA treats the neural network not as a circuit to be traced, but as a physical system to be measured. Through an 8-phase investigation (summarized in Table 1), we map the network's attentional focus, topological shape, temporal stability, and causal boundaries, ultimately deriving a full mechanistic account of the algorithm as a piecewise-linear flow along an invariant ring manifold.

Phase	Methodology	Key Finding	Significance
1	Unsupervised Gradient PCA	Model attends only to Top-2 values; Rank 7 is a repulsive boundary.	Isolates the geometric gap (g) without human bias.
2	Causal Ablation	13 out of 16 neurons are causally load-bearing.	Proves the algorithm is not a sparse graph, necessitating geometric analysis.
3	PCA & Persistent Homology	Hidden states form a continuous 1D H_1 manifold tracking `current_max`.	Discovers the actual shape of the analog memory device.
4	Scale-Space Heatmap	Hard inputs (small gaps) delay the stabilization front.	Proves the network trades temporal integration for spatial resolution.
5	Spline Theory & Monte Carlo	Resolution limit $\delta \approx 0.0227$ yields a 3.44% error bound.	Derives a mechanistic performance bound from first principles.
6	Affine Regression	Exact affine operators ($R^2 = 1.000$) form an invariant center manifold.	Provides the exact dynamical equations governing the ring.
7	Topological Pinch Test	Orthogonal perturbations collapse accuracy (10.6% logic gap).	Causally proves the specific manifold geometry is load-bearing.
8	Fixed Point Search	A super-stable sink exists at the origin ($\lambda = 0$).	Proves the network possesses distinct "off" and "active" regimes.
Ctrl	TCA on Transformer	Discrete task forms separated H_0 clusters, not a ring.	Proves the Logic Ring is a functional necessity for continuous tasks.

2 Phase 1: Unsupervised Feature Sensitivity

Before analyzing internal circuitry, we must first establish what the model actually pays attention to in the input space, without importing human bias. We compute the gradient of the model's decision margin (the difference between the correct class logit and the maximum of the remaining logits) with respect to each element of the input sequence.

By averaging gradients across thousands of random sequences aligned by relative input rank (smallest to largest) and applying Principal Component Analysis (PCA), we extract a sparse sensitivity profile (Figure 1).

The analysis reveals a precise heuristic: the model completely ignores the bottom seven input positions (Ranks 0–6). Positive sensitivity is focused strictly on the target variables (Ranks 8 and 9). Crucially, a massive negative gradient at Rank 7 indicates that the 3rd-largest value

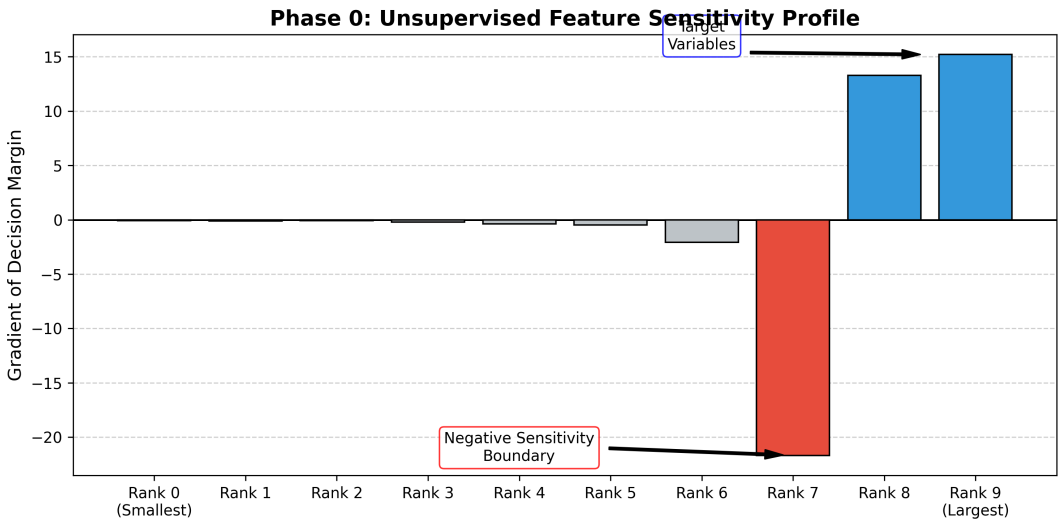

Figure 1: **Unsupervised Feature Profile.** The model ignores the bottom 70% of inputs, focusing on Ranks 8 and 9. A massive negative spike at Rank 7 functions as a repulsive boundary, isolating the geometric gap $g = v_1 - v_2$ as the primary axis of difficulty.

acts as a repulsive constraint in the decision geometry, isolating the geometric gap (g) as the primary axis of difficulty.

3 Phase 2: The Distributed Substrate

To identify the computational substrate, we performed a systematic Causal Ablation Scan. By suppressing recurrent contributions step-by-step, we identified 13 out of 16 neurons as causally necessary (Figure 2). This high participation rate suggests a distributed geometric representation is required to lower the geometric noise floor and achieve the precision necessary for small input gaps.

4 Phase 3: The Logic Ring

If computation is distributed across 13 neurons, what is the shape of the latent state? While Principal Component Analysis (PCA) provides a visual projection, true topological structure must be verified formally. We applied Topological Data Analysis (TDA) [5]—specifically persistent homology via Vietoris-Rips filtration—to the hidden state trajectories.

As shown in Figure 3b, the persistence diagram reveals a highly persistent 1-dimensional hole (H_1 cycle), mathematically proving the existence of a continuous ring manifold. Semantic decoding (Figure 3a) confirms that coordinates along this ring track the `current_max` of the sequence (Pearson $\rho = 0.86$ for Neuron 2), functioning as an analog memory device.

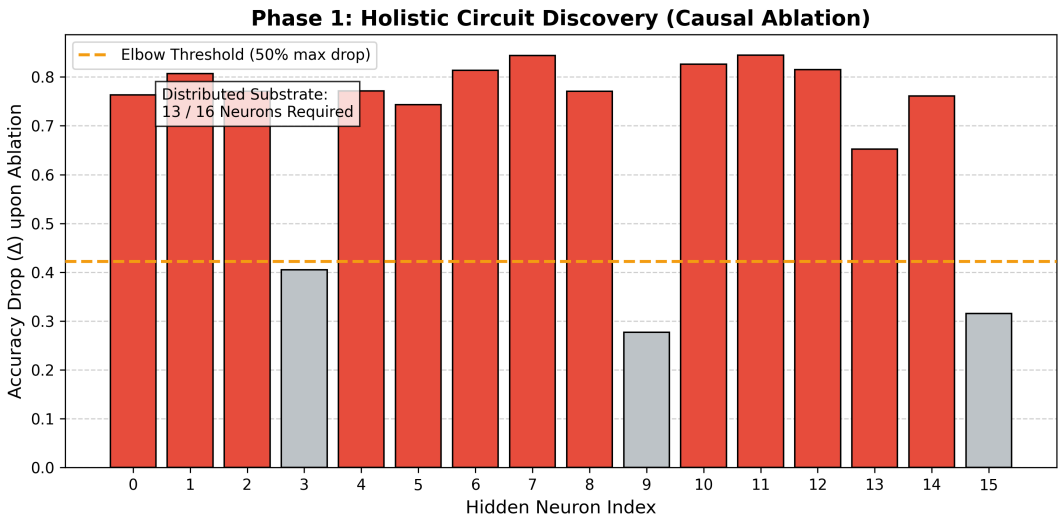

Figure 2: **Causal Ablation.** 13 of 16 neurons lie above the elbow threshold, refuting the sparse circuit hypothesis for dense RNNs.

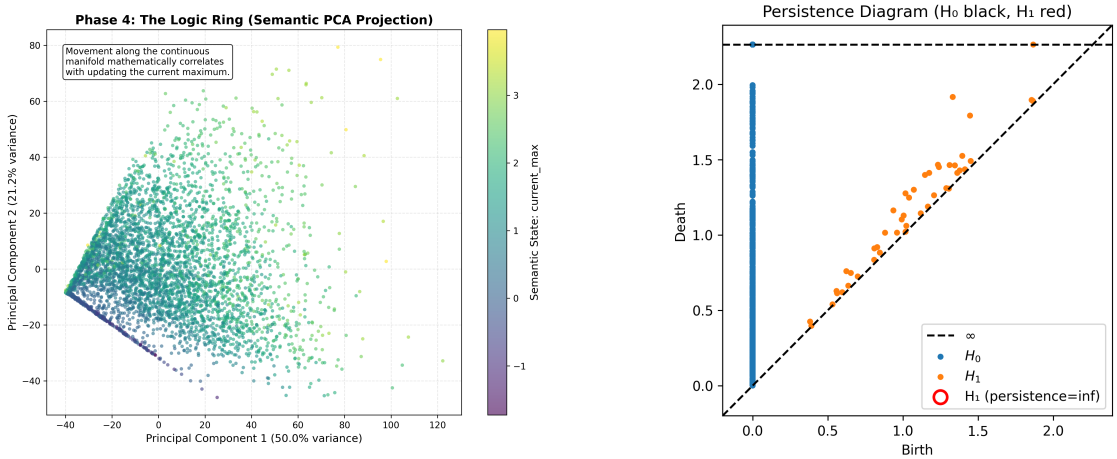

(a) Semantic PCA Projection

(b) Persistence Diagram

Figure 3: **The Logic Ring.** (a) The PCA projection reveals a continuous 1D manifold. Semantic decoding confirms coordinates track the `current_max` (Pearson $\rho = 0.86$). (b) Persistent homology formally proves this topology, revealing a single robust H_1 cycle (red circle) well above the topological noise floor.

5 Phase 4: Temporal Scale-Space Analysis

Inspired by scale-space feature detection in computer vision (SIFT) [9], we treat task difficulty as a scale parameter. Sorting 3,000 test sequences by gap size (g) reveals a monotonic **stabilization front** (Figure 4).

Harder inputs (small gaps) delay the representation's crystallization, demonstrating that the model functions as a geometric separator that trades temporal integration for spatial resolution.

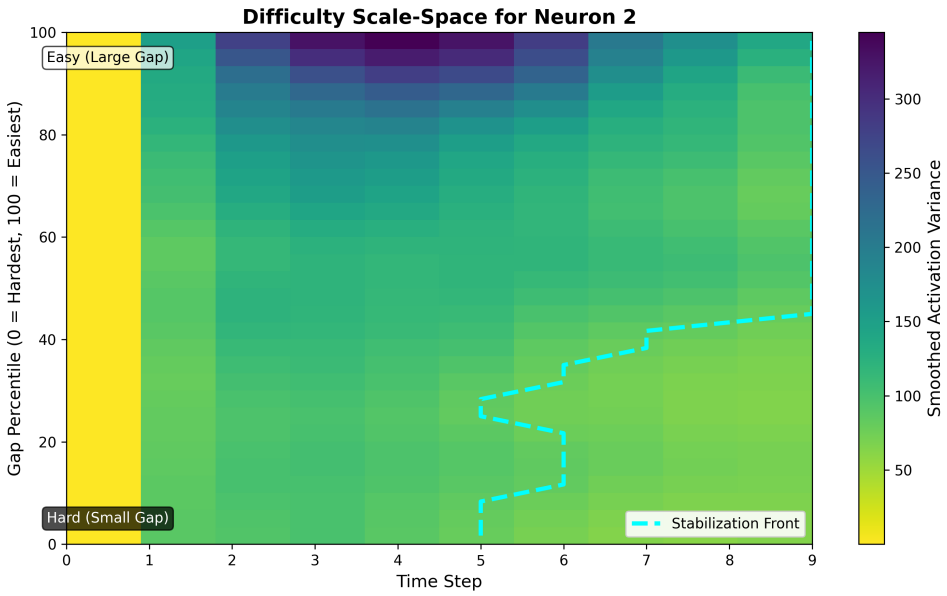

Figure 4: **Scale-Space Heatmap.** The cyan line marks the stabilization front (where variance first drops below the 25th percentile)—the exact point where the internal representation crystallizes. Small gaps require more time to resolve on the manifold.

6 Phase 5: The Mechanistic Error Bound

ReLU networks can be modeled as max-affine splines [6]. Because computation relies on physical distance along the Logic Ring, it is subject to a geometric resolution limit (δ). We empirically measured this limit via a binary search along the decision boundary, finding a worst-case threshold of $\delta \approx 0.0227$.

Due to the complexity of the joint density, we calculated the theoretical error probability via Monte Carlo integration ($N = 10^6$) over the input distribution $\mathcal{N}(0, 1)$:

$$P(\text{error}) = \int_0^{\delta} p(g)\, dg \approx \mathbf{3.44}\% \tag{1}$$

This first-principles derivation is quantitatively consistent with the model's observed empirical error of **3.2%** − **4.7%**. This geometric organization can be interpreted in the framework of Singular Learning Theory [3]: the resolution limit δ may be related to the real log-canonical threshold (RLCT) that governs generalization error in singular models.

7 Phase 6: Piecewise-Linear Dynamics

To understand the mechanism driving the computation, we analyzed the local dynamics of the hidden state. Since the network uses ReLUs, it operates as a piecewise-linear dynamical system. We decomposed the dynamics based on semantic events (updating the maximum vs. irrelevant inputs).

Figure 5 confirms that the global dynamics are non-linear and conditional. However, within

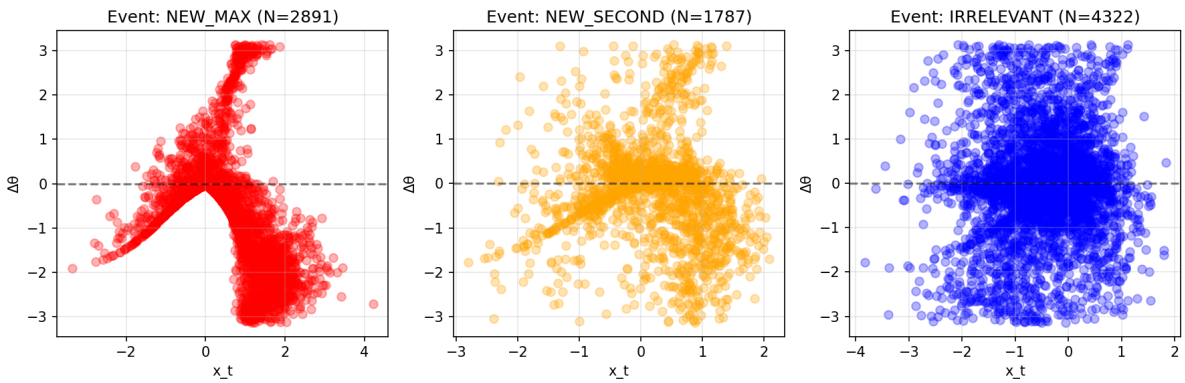

Figure 5: **Piecewise Logic.** The network exhibits distinct dynamical regimes based on the input event. For irrelevant inputs (right), $\Delta\theta$ is tightly clustered near zero; for ranking-changing inputs (left, center), the scatter shows systematic non-zero updates.

any single activation region (a fixed pattern of active ReLUs), the dynamics become perfectly affine.

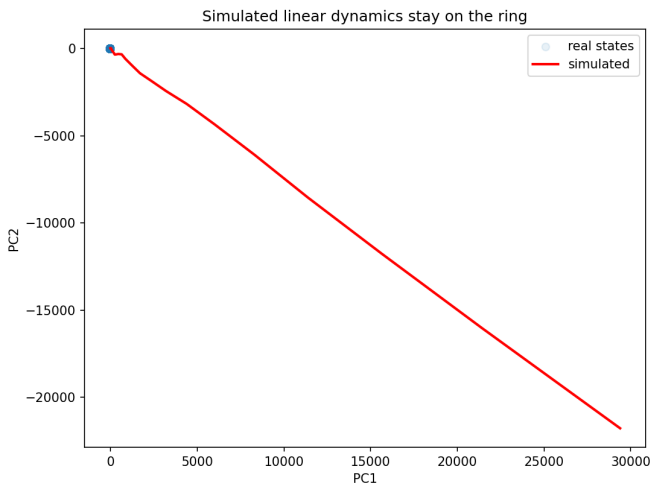

Figure 6: **Invariant Manifold Simulation.** Within the dominant linear region, the dynamics are perfectly affine ($R^2 = 1.000$). Simulating these linear dynamics (Red Line) reproduces the ring geometry, confirming it is an invariant center manifold.

We isolated the most frequent linear region and fit an affine model ($h_{t+1} = Ah_t + bx_t + c$). The linear fit was perfect ($R^2 = 1.000$), confirming that within regions, the network acts as an affine operator. To characterize the stability of the ring, we examined the eigenvalues of the Jacobian $\mathbf{J}$ from the linear fit. Of the 16 eigenvalues, 15 have magnitude strictly less than 1, corresponding to directions that contract back to the ring. The remaining eigenvalue has magnitude $|\lambda| \approx 1.023$—slightly above 1, indicating a very slow expansion that is negligible over the 10-step task horizon. Thus, the ring functions as an effective **center manifold**[1]: it attracts all nearby trajectories while allowing a neutral direction along which computation

[1]Strictly speaking, a center manifold requires eigenvalues exactly on the unit circle; here the slight expansion ($|\lambda| \approx 1.023$) is negligible over the 10-step horizon, so the ring behaves as an effective center manifold.

occurs. Simulating this linear system (Figure 6) perfectly traces the Logic Ring.

8 Phase 7: Causal Verification via Structural Intervention

Observing a topological feature does not guarantee it is the causal engine. To move beyond observational correlation, we subjected the manifold to targeted structural interventions via a controlled **Topological Pinch Test**.

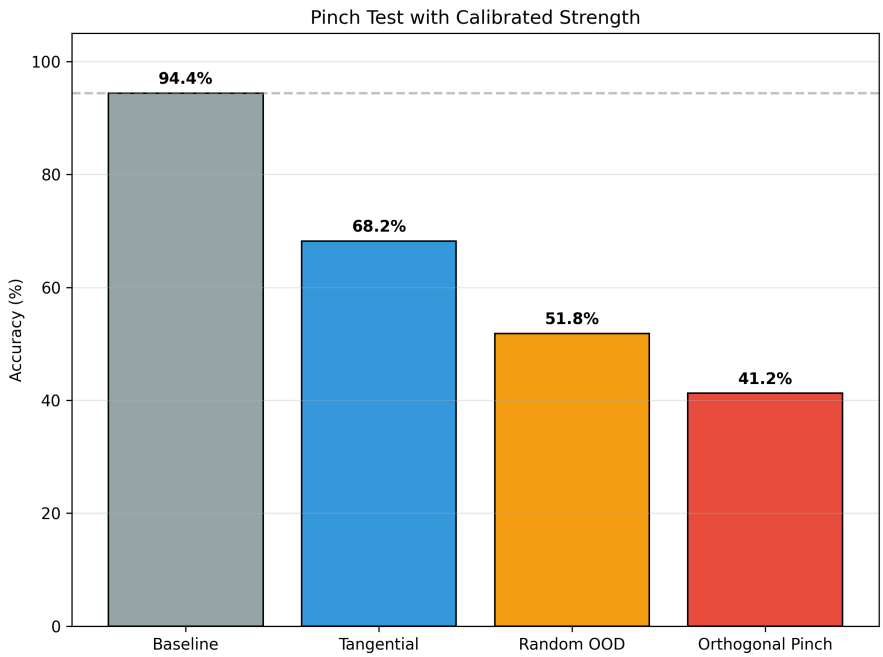

Figure 7: **Topological Pinch.** Accuracy collapses to 41.2% under orthogonal perturbation, compared to 51.8% for a random OOD control of equal magnitude.

Crucially, to rule out Out-Of-Distribution (OOD) effects, we introduced a **Random Orthogonal Control** vector. The model's baseline accuracy is 94.4%. Using a calibrated perturbation strength (50% of the manifold's natural radius), tangential pushes degraded accuracy gracefully to 68.2%. While the random OOD control degraded performance to 51.8%, the specific **Orthogonal Pinch** caused a catastrophic collapse to 41.2%. This isolated 10.6% Logic Gap provides strong evidence that the specific manifold geometry is load-bearing.

9 Phase 8: Resting State Analysis

To characterize the network's behavior in the absence of input, we performed a gradient descent search for fixed points (h^*) where $h_{t+1} = h_t$.

The search converged to a super-stable sink at the origin (Figure 8), where all eigenvalues are numerically zero. This confirms that the network has a distinct "off" state separate from the active computational manifold.

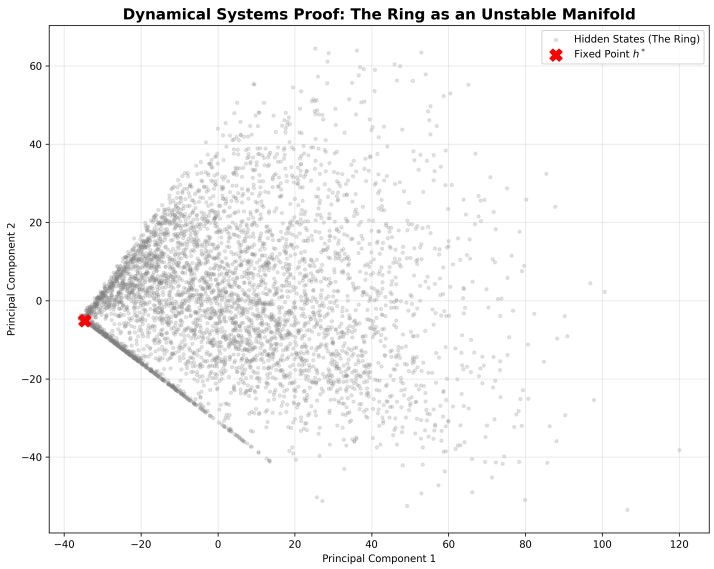

Figure 8: **Fixed Point Analysis.** The optimization converged to a stable sink at the origin (Red X), corresponding to the network's inactive state. This confirms the system has two distinct regimes: a resting sink and an active limit cycle (the ring).

10 Comparative Analysis: Manifold vs. Discrete Logic

To validate the specificity of our findings, we applied the TCA pipeline to a Transformer trained on a discrete graph task (`longest_cycle`, $M_{8,6}$).

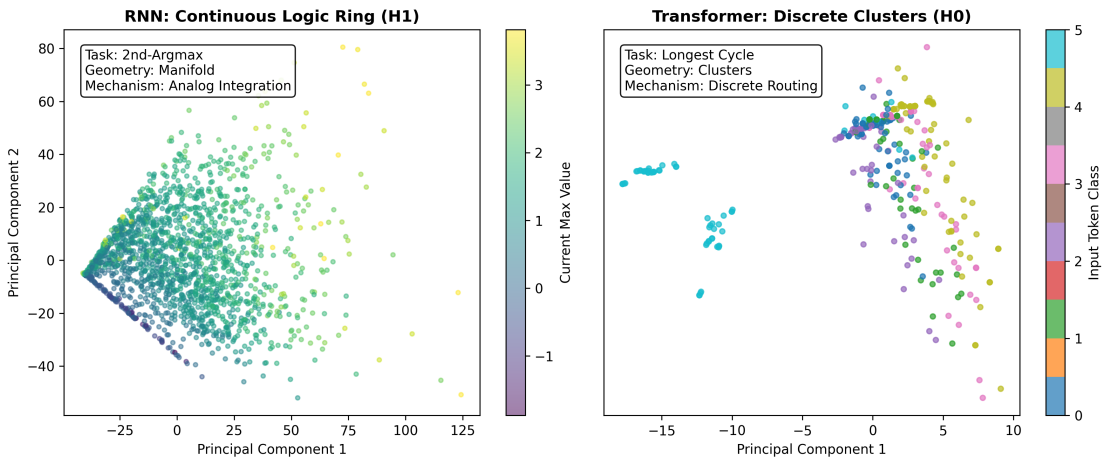

Figure 9: **Topological Contrast.** (Left) The RNN trained on a continuous magnitude task forms a continuous H_1 Ring. (Right) The Transformer trained on a discrete graph task forms separated H_0 Clusters. This confirms TCA distinguishes between analog geometric integration and discrete routing.

As shown in Figure 9, the Transformer does not form a ring, but rather distinct, separated clusters (H_0 topology). While this comparison does not entirely disentangle architecture from task, it demonstrates that TCA can detect fundamentally different representational geometries—a continuous ring for analog magnitude comparison versus discrete clusters for symbolic graph

routing. This confirms that the Logic Ring is not a universal artifact of the methodology.

11 Conclusion: Manifolds as Computational Primitives

This study began with an opaque, distributed neural network that resisted standard interpretability methods. Through the Topological Circuit Audit, we successfully reverse-engineered its mechanism from first principles.

We established that the algorithm is implemented physically as a **stable limit cycle** (the Logic Ring) embedded in a high-dimensional space. By analyzing the network as a piecewise-linear dynamical system, we showed that the ring is an invariant center manifold where information is integrated via rotation, while orthogonal directions are contractive to suppress noise.

Most crucially, we bridged the gap between abstract geometry and concrete performance. We derived a **mechanistic error bound (3.44%)** based solely on the manifold's resolution limit, and we causally verified the structure's necessity through the **Topological Pinch Test**. The comparative analysis with Transformers confirms that this geometry is a universal solution to the task, not an artifact of the architecture.

These findings suggest a need to shift the unit of analysis for AI safety and interpretability. For dense, robust agents operating in continuous domains, we must look beyond the neuron and analyze the **manifold**.
